Matlab code used for task 1.1 and 1.2

 ${\rm Task}~1.1$

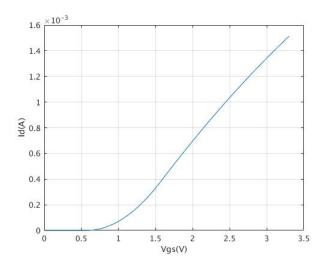

Figur 1. Linear plot of Vgs as a function of Id

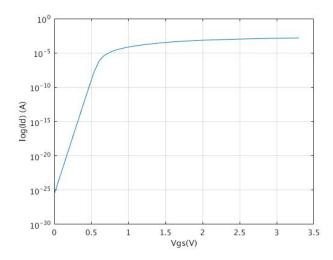

Figur 2. Log plot of Vgs as a function of Id

As long as $V_{ds} > V_{ov}$ the transistor will be in the active region. As long as $V_{gs} < V_{tn}$ the transistor is off. This means that the active region is when $V_{gs} > V_{tn}$. V_d is set higher than $V_{gs(max)}$. That means that no matter how high we set V_{ds} , I_{ds} does not get higher than approx. 2.8mA.

Task 1.2

Figur 3. Linear plot of V_{gs} as a function of I_d

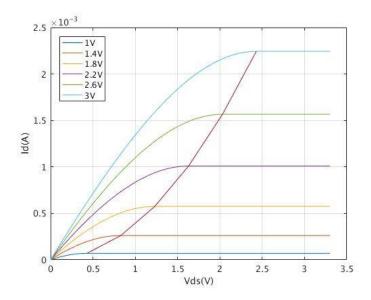

Figur 4. Log plot of V_{gs} as a function of I_d

To ensure that the curve is in the triode region $V_{ov} > V_{ds}$. The transistor needs to be turned on $(V_{gs} > V_{tn})$ for it to be in the triode region.

Matlab code used for task 1.3 and 1.4

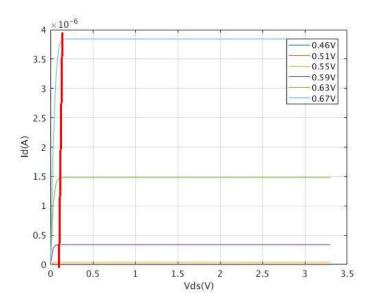

FIGUR 5. Plot of different voltages for Vgs. The line that grows exponentially marks where:

$$V_{ds} - V_{ov} < 50mV$$

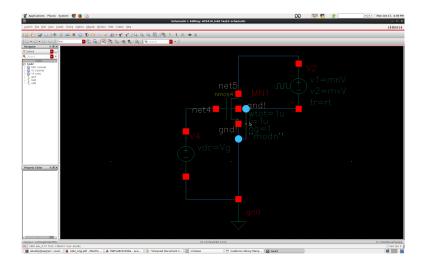

This means that every point left of the line is in triode region and every point right of the line is in saturation.

 $Task\ 1.4$

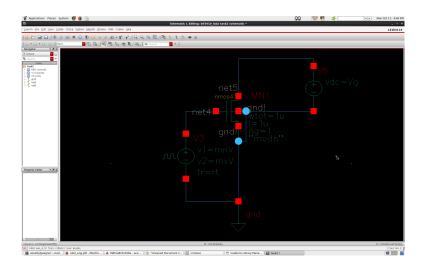

FIGUR 6. To ensure that the curve is in weak inversion we sweep V_{gs} within $\pm 100 \mathrm{mV}$ of V_{tn} . The constant behaviors is due to the EKV-model being inaccurate at this voltage range.

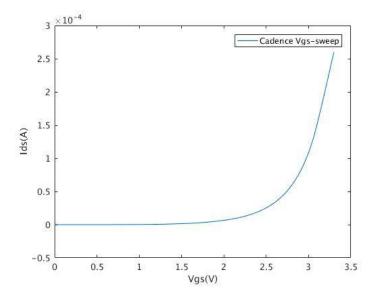

Figur 7. V_{ds} sweep configuration in cadence.

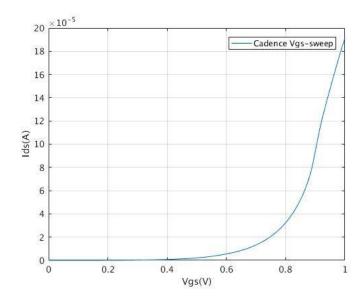

Figur 8. V_{gs} sweep configuration in cadence.

 \sum

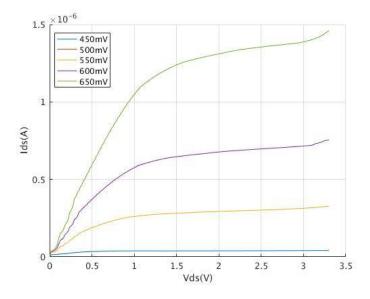

Figur 9. Cadence V_{gs} sweep of the saturation region (Linear).

Figur 10. Cadence V_{gs} sweep of the triode region (Linear).

Figur 11. Cadence V_{ds} sweep of the strong inversion (Linear).

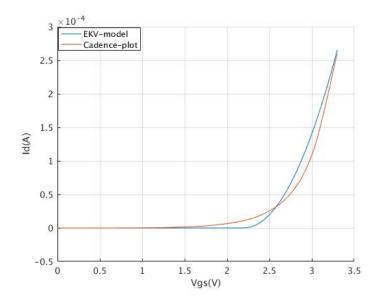

Figur 12. Cadence V_{ds} sweep of the weak inversion (Linear).

In the weak inversion plot we had some problems with plotting $450 \mathrm{mV}$ and $550 \mathrm{mV}$. Somehow we got the same plot for the two, although the numbers provided by cadence was different from each other.

Matlab code used in task 6.

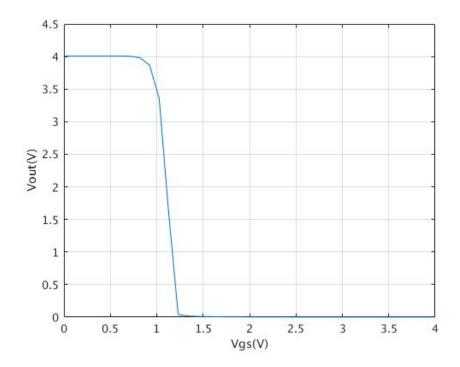

FIGUR 28. $R_D=4,7k\Omega.$ For this common source amp a V_{GS} that would bias the linear range nicely would be around 2V. The bias current at this point can be calculated using Ohm's law, $U=R*I=>I=U/R=>I_D=(V_{dd}-V_{out})/R_D=>I_D=(4V-2V)/4,7k\Omega=0,42553mA.$

We found the gain of the common source amp to be -3,76.

We can see that the common source amp is not in weak inversion. We assume that V_{tn} isn't bigger than 0,6V (couldn't find a threshold voltage in the datasheet for the MC14007UB) and the curve doesn't start falling before $V_{gs}=1,1V$.

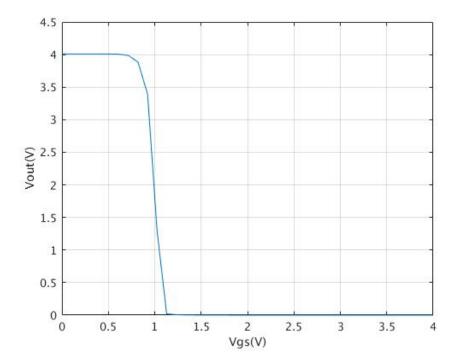

Figur 29. $R_D=680k\Omega$. For this common source amp a V_{GS} that would bias the linear range nicely would be around 1,13V. The bias current at this point can be calculated using Ohm's law. $I_D=(4V-1,13V)/680k\Omega=0,00422mA$

We found the gain of the common source amp to be -16,19.

Using the same assumptions as in the last plot. We see that we're still not in weak inversion.

FIGUR 30. $R_D=3M\Omega$. For this common source amp a V_{GS} that would bias the linear range nicely would be around 1,025V. The bias current at this point can be calculated using Ohm's law. $I_D=(4V-1,025V)/3M\Omega=0,00099mA$

We found the gain of the common source amp to be -20,37.

Using the same assumptions as in the first plot. We can now see that we're close to the threshold, but we're still in strong inversion.

We observe that when R_D has a higher resistance, the gain increases and the bandwidth decreases. The common source amplifier with $R_D=3M\Omega$ has the biggest gain, and the common source amp with $R_D=4,7k\Omega$ has the highest bandwidth.
